Abstract Principles of probability survey design were applied to guide large-scale sampling of populations of stony corals and associated benthic taxa in the Florida Keys coral reef ecosystem. The survey employed a two-stage stratified random sampling design that partitioned the 251-km² domain by reef habitat types, geographic regions, and management zones. Estimates of the coefficient of variation (ratio of standard error to the mean) for stony coral population density and abundance ranged from 7% to 12% for four of six principal species. These levels of survey precision are among the highest reported for comparable surveys of marine species. Relatively precise estimates were also obtained for octocoral density, sponge frequency of occurrence, and benthic cover of algae and invertebrates. Probabilistic survey design techniques provided a robust framework for estimating population-level metrics and optimizing sampling efficiency.

Introduction

Prior to observations of dramatic coral reef declines in Florida, the Caribbean (Gardner et al. 2003), and the Pacific (Done 1999), monitoring programs focused on questions of ecology, addressing how predation, competition, zonation, and disturbance affected coral community dynamics (e.g., Loya 1972; Lang 1973; Connell 1973). Typically, these studies were conducted at single reefs or were restricted to a limited number of habitat types. Still, much was learned about processes affecting the structure and dynamics of coral reefs (Grigg and Maragos 1974; Burns 1983). By the 1980s, monitoring programs adopted many of the methods and statistics of experimental ecology to assess population status and trends. While these programs documented coral declines at specific sites from various causes such as coastal development, pollution, overfishing, and coral disease and bleaching (Brown and Howard 1985; Glynn 1996; Knowlton 2001), none were conducted in a manner that allowed extrapolation from a single or a few reefs being monitored to the population level.

Interestingly, field methodologies and statistical designs used to monitor and assess coral

Technical Series Report (submitted)

Coral project team: Assessment of coral population abundance and distribution

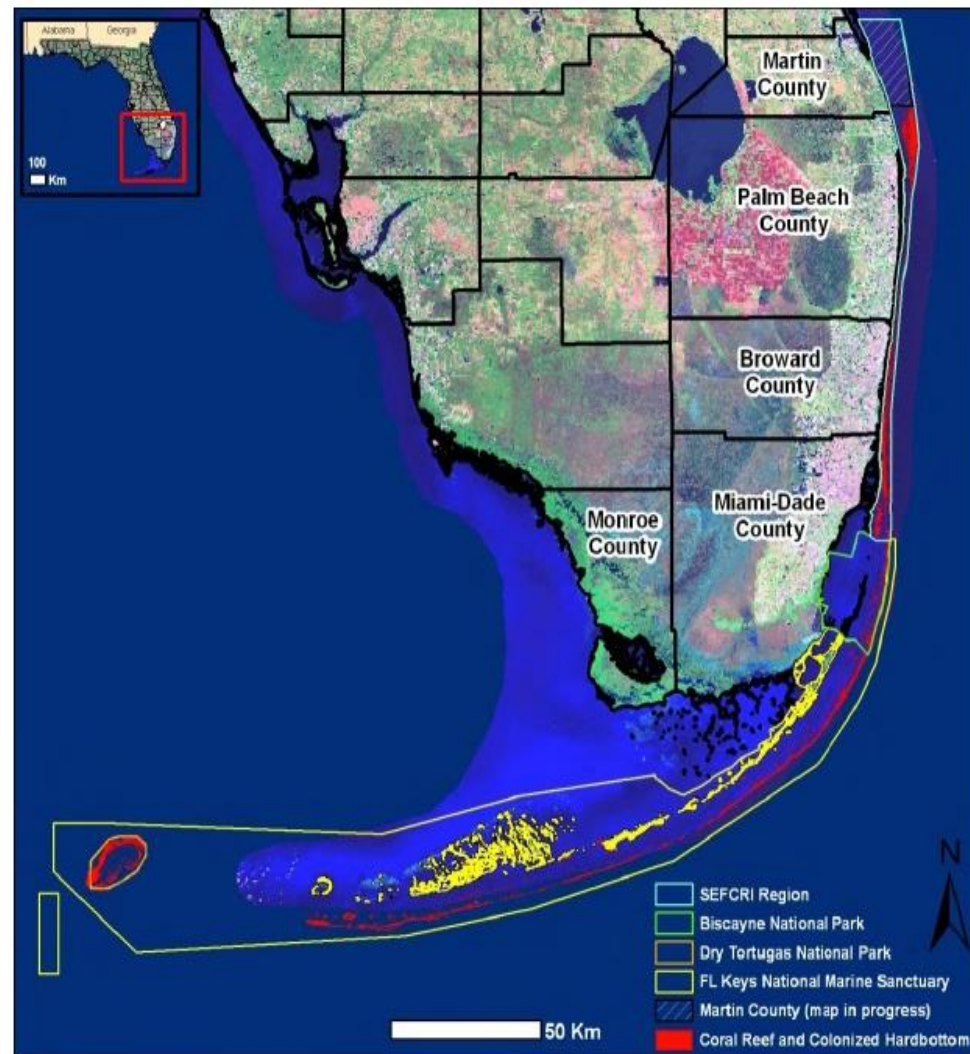

Goals:

- 1. To effectively assess the status threatened coral populations**
 - Quantitative assessment of coral populations in U.S waters using habitat use analysis
- 2. Provide information to managers about the status of threatened coral populations**
 - Develop a useable tool for managers that translates the analytical results
- 3. Evaluate survey performance to inform future survey efforts**

Fundamental concepts

Regulatory factors: physical and biological, natural and anthropogenic, beneficial and detrimental

collectively regulate demographic rate processes

Resource Selection Theory: The strategies used by a species to occupy habitat-space have been found to be closely intertwined with mechanisms of population regulation and persistence through time (**demographic rate processes: growth, survival, and recruitment**).

Assessment of coral populations using habitat use analysis:

- provides estimates of abundance and variance
- inference about how growth-survival varies across ecosystem space

Post-stratification: Habitat use

Sampling strata

Species-specific habitat strata

Population and stratum-specific estimates

- Abundance
- Size structure

Density and proportion occurrence relative to area weighted domain mean

Habitat use determination

Habitat use	Area and abundance comparison
positive	% stratum area < % population abundance
neutral	% stratum area = % population abundance
negative	% stratum area > % population abundance
